ABSTRACT

Transfer learning aims at transferring knowledge from a well-labeled domain to a similar but different domain with limited or no labels. Unfortunately, existing learning-based methods often involve intensive model selection and hyperparameter tuning to obtain good results. Moreover, cross-validation is not possible for tuning hyperparameters since there are often no labels in the target domain. This would restrict wide applicability of transfer learning especially in computationally-constraint devices such as wearables. In this paper, we propose a practically *Easy Transfer Learning (EasyTL)* approach which requires no model selection and hyperparameter tuning, while achieving competitive performance. By exploiting intra-domain structures, EasyTL is able to learn both non-parametric transfer features and classifiers. Extensive experiments demonstrate that, compared to state-of-the-art traditional and deep methods, EasyTL satisfies the *Occam's Razor* principle: it is extremely easy to implement and use while achieving comparable or better performance in classification accuracy and much better computational efficiency. Additionally, it is shown that EasyTL can increase the performance of existing transfer feature learning methods.

Index Terms— Transfer Learning, Domain Adaptation, Cross-domain Learning, Non-parametric Learning

1. INTRODUCTION

The success of multimedia applications depends on the availability of sufficient labeled data to train machine learning models. However, it is often expensive and time-consuming to acquire massive amounts of labeled data. Transfer learning (TL), or domain adaptation [12] is a promising strategy to enhance the learning performance on a target domain with few or none labels by leveraging knowledge from a well-labeled source domain. Since the source and target domains have dif-

ferent distributions, numerous methods have been proposed to reduce the distribution divergence [24, 23, 21, 26, 6].

Unfortunately, despite the great success achieved by existing TL methods, it is notoriously challenging to apply them to a real situation since we cannot determine the best TL model and their optimal hyperparameters. The reasons are three-fold. Firstly, most traditional and deep TL methods are *parametric* methods [23, 24, 26, 5] that have to go through an intensively expensive and time-consuming process to tune a lot of hyperparameters (e.g. Fig. 1; MEDA, DANN, and CDAN in Table 1). Secondly, *cross-validation*, which is the most common strategy to select models and tune hyperparameters, is *not available* in TL since there are often no labeled data in the target domain [12]. Thirdly, although the recent AutoML methods can automatically tune the hyperparameters via tree pruning, boosting, or neural architecture search [15], they are unable to handle the different distributions between domains in TL and typically take a long time to converge.

These challenges seriously restrict the real application of TL, especially on small devices that require instant local computing with limited resources such as wearables. Is it possible to develop an easy but powerful TL algorithm to circumvent

model selection and parameter tuning, but have competitive performance, i.e. satisfying **Occam’s Razor** principle [16]?

In this paper, we make the *first* attempt towards addressing this challenge by proposing a practically **Easy Transfer Learning (EasyTL)** approach. EasyTL is able to perform knowledge transfer across domains *without* the need for model selection and hyperparameter tuning (Table 1). By exploiting *intra-domain structures*, EasyTL learns both non-parametric transfer features by *intra-domain alignment* and transfer classifier by *intra-domain programming*. Thus, it is able to avoid negative transfer [12]. Furthermore, EasyTL can also *increase* the performance of existing TL methods by serving as their final classifier via intra-domain programming.

We conduct extensive experiments on public TL datasets. Both visual domain adaptation and cross-domain sentiment analysis demonstrated significant superiority of EasyTL in classification accuracy and computational efficiency over state-of-the-art traditional and deep TL methods. In short, EasyTL has the following characteristics:

- *Easy*: EasyTL is extremely easy to implement and use. Therefore, it eliminates the need for model selection or hyperparameter tuning in transfer learning.
- *Accurate*: EasyTL produces competitive results in several popular TL tasks compared to state-of-the-art traditional and deep methods.
- *Efficient*: EasyTL is significantly more efficient than other methods. This makes EasyTL more suitable for resource-constrained devices such as wearables.
- *Extensible*: EasyTL can increase the performance of existing TL methods by replacing their classifier with intra-domain programming.

2. RELATED WORK

EasyTL significantly differs from existing work in the following three aspects:

Transfer learning. Existing TL methods can be summarized into two main categories: (a) *instance reweighting*, which reuses samples from the source domain according to some weighting technique; and (b) *feature transformation*, which performs subspace learning or distribution adaptation [24, 23, 13, 17, 20]. Unfortunately, these methods are all *parametric* approaches. They depend on extensive hyperparameter tuning through cross-validation for the feature transformation [13, 24], or the prediction model [6, 17], or both [20, 23]. Most methods require multiple iterations of training [20, 24]. The L2T framework [25] is similar to EasyTL in spirit, but L2T is still based on model iteration and parameter tuning. Deep TL methods [8, 9, 19, 5] require heavy hyperparameter tuning. In TL, *cross-validation* is often not available since there are almost no labeled data in the target domain [12]. In contrast, EasyTL is a non-parametric TL approach that directly learns from *intra-domain structures*,

which requires no model selection and hyperparameter tuning and much more efficient than existing methods.

Non-parametric learning. Nearest-neighbor (NN) classifier is the most common non-parametric method. However, NN computes the distance between each sample in two domains, which is more likely to be influenced by domain shift. Naive Bayes NN (NBNN) classifier is used for domain adaptation [18], which still requires hyperparameter tuning and iterations. Nearest Centroid (NC) classifier is based on the distance between each target sample to the class center of the source domain. EasyTL uses a linear programming to get the softmax probabilities (float weights), while NC is basically 0/1 weights. This means that EasyTL could not only consider the relationship between sample and center, but also the relations of other samples. Open set DA [14] has similar idea with EasyTL, while it solves a binary programming and requires other classifiers.

Automated machine learning. Recent years have witnessed the advance of Automated Machine Learning (AutoML) [15]. AutoML produces results without model selection and parameter tuning. However, no existing AutoML frameworks can handle TL tasks since they assume the training and test data are in the same distribution. AutoDIAL [10] is similar to EasyTL, which includes automatic domain alignment layers for deep networks. However, AutoDIAL still requires many parameters in the network to be tuned.

3. EASY TRANSFER LEARNING

We follow the most common TL settings in existing work [23, 24, 26]. We are given a labeled source domain $\Omega_s = \{(\mathbf{x}_i^s, y_i^s)\}_{i=1}^{n_s}$ and an unlabeled target domain $\Omega_t = \{\mathbf{x}_j^t\}_{j=1}^{n_t}$. The feature space $\mathcal{X}_s = \mathcal{X}_t$, label space $\mathcal{Y}_s = \mathcal{Y}_t$, but marginal distribution $P_s(\mathbf{x}_s) \neq P_t(\mathbf{x}_t)$ with conditional distribution $Q_s(y_s|\mathbf{x}_s) \neq Q_t(y_t|\mathbf{x}_t)$. The goal is to predict the labels $\mathbf{y}_t \in \mathcal{Y}_t$ for the target domain.

3.1. Motivation

It is challenging to design a TL method that requires no model selection and hyperparameter tuning. On one hand, a simple NN (Nearest Neighbor) classifier may suffice, while NN suffers in handling the distribution divergence between domains. On the other hand, existing TL methods such as GFK [6] and BDA [20] could reduce the distribution divergence, while they require tuning a lot of hyperparameters. Combining both of them without considering domain structures may easily result in *negative transfer* [12], which dramatically hurts the performance of TL. Currently, there is no such effort.

In this work, we propose a practically *Easy Transfer Learning (EasyTL)* approach to learn non-parametric transfer features and classifier with competitive performance to existing *heavy* methods. In short, to be consistent with *Occam’s Razor* principle [16]. In light of the recent advance

Fig. 2. The procedure of EasyTL. The colored boxes and circles denote samples from the source and target domains. The red line denotes the classifier.

in representation learning [7], incorporating knowledge of locality can greatly improve the representations quality. Therefore, Instead of learning sample-wise distance, EasyTL focuses on exploiting the *intra-domain structure*. The main part of EasyTL is a novel non-parametric *Intra-domain programming* classifier, while remains open for adopting existing methods for *Intra-domain alignment*. Intra-domain programming is able to learn discriminative transfer information from domains. Fig. 2 shows the procedure of EasyTL. In the following sections, we first introduce the proposed intra-domain programming. Then, we show how to adapt a non-parametric feature learning method for intra-domain alignment.

3.2. Intra-domain Programming

Intra-domain programming directly learns a transfer classifier for TL problem and provides reliable likelihood information for intra-domain alignment. We introduce the concept of the *Probability Annotation Matrix*, based on which we can build the non-parametric transfer classifier. Formally, let $c \in \{1, \dots, C\}$ denote the class label, a matrix $\mathbf{M} \in \mathbb{R}^{C \times n_t}$ with its element $0 \leq M_{cj} \leq 1$ is a probability annotation matrix. Here, the entry value M_{cj} of \mathbf{M} indicates the annotation probability of \mathbf{x}_j^t belonging to class c . Fig. 3 illustrates the main idea of \mathbf{M} . There are 4 classes and n_t target samples with example activation values. Similar to the widely-adopted softmax classifier in neural networks, the highest probability value for \mathbf{x}_1^t is 0.4, which indicates that it belongs to C_4 . The same goes for \mathbf{x}_2^t and \mathbf{x}_3^t , etc. The real probability annotation values are to be learned by our proposed approach.

Instead of learning \mathbf{y}^t directly, the algorithm focuses on learning the probability annotation matrix \mathbf{M} . In this way, the cost function can be formalized as:

$$\mathcal{J} = \sum_j^{n_t} \sum_c^C D_{cj} M_{cj}, \quad (1)$$

where the distance value D_{cj} is an entry in a distance matrix \mathbf{D} . D_{cj} denotes the distance between \mathbf{x}_j^t and the c -th class center of the source domain $\Omega_s^{(c)}$.

We denote \mathbf{h}_c as the c -th class center of $\Omega_s^{(c)}$. Then, D_{cj} can be computed by the Euclidean distance:

$$D_{cj} = \|\mathbf{x}_j^t - \mathbf{h}_c\|^2. \quad (2)$$

	\mathbf{x}_1^t	\mathbf{x}_2^t	\mathbf{x}_3^t	$\mathbf{x}_{n_t}^t$
C_1	0.1	0.2	0.5
C_2	0.2	0.4	0.1
C_3	0.3	0.2	0.2
C_4	0.4	0.2	0.2

Fig. 3. An example of the probability annotation matrix.

The class center \mathbf{h}_c on Ω_s can be calculated as:

$$\mathbf{h}_c = \frac{1}{|\Omega_s^{(c)}|} \sum_i^{n_s} \mathbf{x}_i^s \cdot \mathbb{I}(y_i^s = c), \quad (3)$$

where $\mathbb{I}(\cdot)$ is an indicator function which evaluates to 1 if the condition is true, and 0 otherwise.

Consider the constraints to minimize the cost function in Eq. (1). Firstly, note that the value of M_{cj} is a probability measuring the confidence of \mathbf{x}_j^t belonging to class c , such that the sum of the probability of one particular sample \mathbf{x}_j^t belonging to all existing classes is 1. This is ensured by the following constraint:

$$\sum_c^C M_{cj} = 1, \forall j \in \{1, \dots, n_t\}. \quad (4)$$

Secondly, since Ω_s and Ω_t have the same label space (i.e. $\mathcal{Y}_s = \mathcal{Y}_t$), there must be at least one sample for any given class c . This is ensured by the following constraint:

$$M_{cj} = \arg \max_r M_{rj}, r \in \{1, \dots, C\}, \forall c \in \{1, \dots, C\}, \exists j. \quad (5)$$

In fact, the ideal state of M_{cj} should be a binary value (0 or 1), i.e. $M_{cj} = 1$ iff \mathbf{x}_j belongs to class c , otherwise $M_{cj} = 0$. Therefore, we use the following formulation to replace Eq. (5) in the computation without affecting the results:

$$\sum_j^{n_t} M_{cj} \geq 1, \forall c \in \{1, \dots, C\}. \quad (6)$$

Learning objective. Combining the cost function in Eq. (1) and the constraints in Eq. (4) and Eq. (6), the final learning objective becomes:

$$\begin{aligned} \min \quad & \mathcal{J} = \sum_j^{n_t} \sum_c^C D_{cj} M_{cj}. \\ \text{s.t.} \quad & \begin{cases} 0 \leq M_{cj} \leq 1 \\ \sum_c^C M_{cj} = 1, \forall j \in \{1, \dots, n_t\} \\ \sum_j^{n_t} M_{cj} \geq 1, \forall c \in \{1, \dots, C\} \end{cases} \end{aligned} \quad (7)$$

Solving Eq. (7) requires us to solve a linear programming (LP) problem. There are existing solution packages such as PuLP¹ for solving the above linear programming

¹<https://pypi.python.org/pypi/PuLP/1.1>

problem efficiently. Then, \mathbf{M} can be obtained. Eventually, the label of \mathbf{x}_j^t is given by the softmax function:

$$y_j^t = \arg \max_r \frac{M_{rj}}{\sum_c M_{cj}} \quad \text{for } r \in \{1, \dots, C\}. \quad (8)$$

It is noticeable that this classifier does **not** involve any parameters to tune explicitly. This is significantly different from well-established classifiers such as SVM that needs to tune numerous hyperparameters. In fact, intra-domain programming can be used alone for TL problems.

3.3. Intra-domain Alignment

Intra-domain alignment serves as the transfer feature learning methods for EasyTL. Although EasyTL can be used directly in TL with good performance, it can also be combined with transfer feature learning to eliminate feature distortions in the original space. On the other hand, existing transfer feature learning methods can also be extended using the previous *intra-domain programming* to enhance their performance.

Recall our inspiration that learning the structure of locality will help learn useful representations [7]. Therefore, if we perform *personalized* transfer feature learning within each subspace, we could further reduce the domain divergence. For simplicity and efficiency, we only perform feature learning from the source domain to the subspace of the target domain.

Inspired by the non-parametric feature learning method CORAL [17], the intra-programming process of EasyTL can be formulated as:

$$\mathbf{z}^r = \begin{cases} \mathbf{x}^r \cdot (\text{cov}(\mathbf{x}^s) + \mathbf{E}_s)^{-\frac{1}{2}} \cdot (\text{cov}(\mathbf{x}^t) + \mathbf{E}_t)^{\frac{1}{2}} & \text{if } r = s \\ \mathbf{x}^r & \text{if } r = t \end{cases} \quad (9)$$

where $\text{cov}(\cdot)$ is the covariance matrix. \mathbf{E}_s and \mathbf{E}_t are identity matrices with equal sizes to Ω_s and Ω_t , respectively. We can treat this step as a *re-coloring* process of each subspace [17]. Eq. (9) aligns the two distributions by re-coloring whitened source features with the covariance of target distributions.

Remark: Other than CORAL, EasyTL can also choose other popular methods for feature learning such as BDA [20] and GFK [6]. We choose CORAL for its computational efficiency and that it contains no other parameters to tune.

3.4. Computational Complexity

We use the big- O notation to analyze the complexity of EasyTL. Intra-domain alignment takes at most $O(Cn_s^3)$. The complexity of intra-domain programming is $O(n_t^3 C^3)$ given that it is a linear programming problem (Eq. (7)) [11]. EasyTL can be made more efficient with the low-rank representations and other fast computing algorithms.

As an intuitive comparison of classifiers, we compare intra-domain programming with the well-established SVM. A *single* round of SVM training and prediction takes $O((n_s +$

Algorithm 1 EasyTL: Easy Transfer Learning

Input: Feature matrix $\mathbf{x}_s, \mathbf{x}_t$ for Ω_s and Ω_t , respectively; and label vector \mathbf{y}_s for Ω_s

Output: Predicted label vector \mathbf{y}_t for target domain.

- 1: (Optional) Perform intra-domain alignment via Eq. (9)
 - 2: Solve Eq. (7) to obtain the probability annotation matrix \mathbf{M} and compute \mathbf{y}_t using Eq. (8)
 - 3: **return** Label vector \mathbf{y}_t for Ω_t
-

n_t)³ computations [1]. This implies that the time complexity of intra-domain programming is comparable to a single round of SVM. However, SVM still needs a couple of rounds for hyperparameter tuning (e.g. *kerneltype, constraints*) before getting optimal performance. Therefore, EasyTL is theoretically more efficient than SVM. We will experimentally show the efficiency of EasyTL in the next sections.

4. EXPERIMENTAL EVALUATION

4.1. Experimental Setup

We use four popular TL datasets: 1) **Amazon Review** [2] is a cross-domain sentiment analysis dataset that contains positive and negative reviews of four kinds of products: Kitchen appliance (K), DVDs (D), Electronics (E), and Books (B). 2) **Office-Caltech** [6] contains 10 common classes of images in Amazon (A), DSLR (D), Webcam (W), and Caltech (C). 3) **Image-CLEF DA** [9] contains 12 categories of images belonging to 3 domains: Caltech (C), ImageNet (I), and Pascal (P). 4) **Office-Home** [19] contains 15,500 images of 65 categories from 4 domains: Art (Ar), Clipart (Cl), Product (Pr), and Real-world (Rw). Within each dataset, any two domains can be source and target to construct TL tasks.

State-of-the-art traditional and deep comparison methods: **NN** (Nearest Neighbor), **SVM** with linear kernel [17], **TCA** (Transfer Component Analysis) [13], **GFK** (Geodesic Flow Kernel) [6], **SA** (Subspace Alignment) [4], **CORAL** (CORrelation ALignment) [17], **BDA** (Balanced Distribution Adaptation) [20], **JGSA** (Joint Geometrical and Statistical Alignment) [26], **D-GFK** [24], **ResNet50**, **DANN** (Domain-adversarial Neural Networks) [5], **JAN** (Joint Adaptation Networks) [9], and **CDAN** (Conditional Adversarial Adaptation Networks) [8]. The source code of EasyTL is available at <http://transferlearning.xyz/code/traditional/EasyTL>.

Specifically, we use *EasyTL(c)* to denote intra-domain programming since it can serve as a TL method alone, while *EasyTL* denotes the full method. By following the standard protocol in [17], we adopt linear SVM for traditional TL methods. For the amazon dataset, we use the 400-dimensional features [22]. For image datasets, we use the 2048-dimensional ResNet50 finetuned features [22]. For Office-Caltech datasets, we adopt the SURF features [24].

Deep TL methods are only used in image datasets whose results are obtained from existing work. Classification accuracy is acting as the evaluation metric [13, 6, 17].

4.2. Results: Accuracy and Efficiency

The results on Amazon Review is shown in Table 3. Table 2 shows the results on ImageCLEF DA (IDs 1~6) and Office-Home (IDs 7~18). Results on Office-Caltech are in the code page due to space limit. We also report the average rank [3], parameter and running time (train+test) of several methods in Table 4. The results demonstrate that EasyTL outperforms all comparison methods in both sentiment and image data. EasyTL(c) can also achieve competitive performance than most methods. Note that except INN and EasyTL, other methods all require hyperparameter tuning. It clearly indicates the superiority of EasyTL in accuracy and efficiency.

There are more insightful findings. 1) On the larger and more challenging Office-Home dataset, the performance of EasyTL(c) is only slightly worse than CDAN, while it outperforms all other comparison methods. Compared to deep TL methods (DANN, JAN, and CDAN), although EasyTL takes finetuned features as inputs, it only requires *one* distinct fine-

Table 4. Average rank, parameter, and running time

Method	TCA	GFK	CORAL	DANN	CDAN	EasyTL(c)	EasyTL
Avg rank	9	10	8	4	2	<u>3</u>	1
Parameter	d, λ, C, γ	d, C, γ	C, γ	λ	λ	None	None
Time (s)	119	127.4	126.5	>1000	>1000	23.8	59.6

tuning process while deep methods have to run the network multiple times to get optimal parameters. 2) Moreover, in real applications, it is rather difficult and almost *impossible* to search parameters since there are often little or none labeled data in the target domain. It seems that adversarial learning provides little contribution on TL compared to the power of ResNet in representation learning, and it is rather difficult to train an adversarial network. 3) The results imply that the “2-stage” procedure (finetune+EasyTL) is better than “1-stage” methods (deep TL) even if they are end-to-end. All methods have their advantages and disadvantages. 4) EasyTL tends to perform consistently well on rather balanced datasets (Amazon Review and Image-CLEF DA). While on the unbalanced Office-Caltech dataset, the performance of EasyTL is limited. The research of improving EasyTL for unbalanced datasets remains as future research.

4.3. Evaluation of Extensibility

We evaluate the extensibility of EasyTL by extending existing TL methods with the classifier of EasyTL. We use PCA, TCA [13], GFK [6], and CORAL [17] for intra-domain alignment and compare the performance of +SVM and +EasyTL in Fig. 4. The results show that: 1) By using feature learning methods other than CORAL, EasyTL can still achieve comparable performance to existing approaches. 2) More importantly, EasyTL does **not** rely on any particular feature learning methods to achieve good performance. 3) EasyTL can *increase* the performances of existing TL methods. It clearly implies the extensibility of EasyTL in transfer learning.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we propose EasyTL as the first non-parametric transfer learning approach by exploiting intra-domain structures features to learn non-parametric transfer features and classifiers. Thus, it requires no model selection and hyperparameter tuning. EasyTL is easy, accurate, efficient, and extensible, and can be applied directly in the resource-constrained devices such as wearables. Experiments demonstrate the superiority of EasyTL in accuracy and efficiency over several popular traditional and deep TL methods. EasyTL can also increase the performance of other TL methods.

EasyTL opens up some new research opportunities in TL:

Practical Transfer Learning. Instead of pursuing good performance in accuracy, we do hope that EasyTL could open up a new door in research on practical transfer learning that focuses more on the actual usage of the methods: parameter tuning and model validation.

Automated Domain Selection. Currently, EasyTL focuses on *how to transfer*. In real applications, another important problem is *what to transfer*. Some existing work focused on this issue, but they also require heavy parameter tuning. We will further explore this part by extending EasyTL.

Multi-label Transfer Learning. EasyTL can be used in multi-label transfer learning by changing the value of probability annotation matrix. This makes EasyTL suitable for multi-label tasks. Existing multi-label transfer methods have to modify their classifiers. EasyTL can be more advantageous for these applications.
